Abstract. Software testing is a very important activity in the software development life cycle. Numerous general black- and white-box techniques exist to achieve different goals and there are a lot of practices for different kinds of software. The testing of embedded systems, however, raises some very special constraints and requirements in software testing. Special solutions exist in this field, but there is no general testing methodology for embedded systems. One of the goals of the CIRENE project was to fill this gap and define a general testing methodology for embedded systems that could be specialized to different environments. The project included a pilot implementation of this methodology in a specific environment: on an Android-based Digital TV receiver (Set-Top-Box). In this pilot, we implemented method level code coverage measurement of Android applications. This was done by instrumenting the applications and creating a framework for the Android device that collected basic information from the instrumented applications and communicated it through the network towards a server where the data was finally processed. The resulting code coverage information was used for many purposes according to the methodology: test case selection and prioritization, traceability computation, dead code detection, etc.

In this paper, we introduce this pilot implementation and, as a proof-of-concept, present how the coverage results were used for different purposes.

1 Introduction

Software testing is a very important quality assurance activity of the software development life cycle. With testing, the risk of a residing bug in the software can be reduced, and by reacting to the revealed defects, the quality of the software can be improved. Testing can be performed in various ways. Static testing – for example – can be performed on any workproducts of the project; it includes the manual checking of documents and the automatic analysis of the source code without executing the software. During dynamic testing the software or a specific part of the software is executed. Many dynamic test design techniques exist, the two most well known groups among them are black-box and white-box techniques.
Black-box test design techniques concentrate on testing functionalities and requirements by systematically checking whether the software works as intended and produces the expected output for a specific input. The techniques take the software as a black box, examine what the program does without having any knowledge on the structure of the program, and they are not interested in the question how.

On the other hand, white-box testing examines the question How does the program do that, and tries to exhaustively examine the code from several aspects. This exhaustive examination is given by a so-called coverage criterion which defines the conditions to be fulfilled by the set of instruction sequences executed during the tests. (E.g. 100% instruction coverage criterion is fulfilled if all instructions of the program are executed during the tests.) Coverage measures give a feedback on the quality of the tests themselves.

The reliability of the test can be improved, by combining black-box and white-box techniques. During the execution of test cases generated from the specifications using black-box techniques, white-box techniques can be used to measure how completely the actual implementation is checked. If necessary, reliability of the tests can be improved by generating new test cases for the not verified code fragments.

1.1 Specific problems with embedded system testing

Testing in embedded environments has special attributes and characteristics. Embedded systems are neither uniform nor general-purpose. Each embedded system has its own hardware and software configuration typically designed and optimized for a specific task, which affects the development activities on the specific system. Development, debugging, and testing are more difficult since different tools are required for different platforms.

However, high product quality and testing that ensures this high quality is very important as the correction of residual bugs can be very difficult for these systems. For example, the software of a digital TV with play-from-USB capabilities fails to recover after opening a specific media file format and this bug can only be repaired by replacing the ROM of the TV. Once the TV's are produced and sold, it might be impossible to correct this bug without spending a huge amount of money on logistic issues. Although there are some solutions aiming at the uniformisation of the software layers of embedded systems (e.g. the Android platform [1]), there has not been a uniform methodology for embedded systems testing.

1.2 The CIRENE project

One of the goals of the CIRENE project [2] is to fill this gap and define a general testing methodology for embedded systems that copes with the above mentioned specialities and whose parts can be implemented on specific systems. The methodology combines black-box tests responsible for the quality assessment of the system under test and white-box tests responsible for the quality assessment
of the tests themselves. Using this methodology the reliability of the test results and the quality of the embedded system can be improved. As a proof-of-concept, the CIRENE project included a pilot implementation of the methodology for a specific, Android-based digital Set-Top-Box system. Although the proposed solution was developed for a specific embedded environment, it can be used for any Android-based embedded devices such as smart phones or more general-purpose tablets.

The methodology specialized to the Set-Top-Box in the pilot implementation can be seen on Figure 1. The coverage measurement toolchain plays an important role in the methodology. Many coverage measurement tools (e.g. EMMA [3]) exist that are not specific but can be used on Android applications. However, these are applicable only during the early development phases as they are able to measure code coverage on the development platform side. This kind of testing omits to test the real environment, misses the hardware-software co-existence issues which can be essential in embedded systems. We are not aware of any common toolchain that measures code coverage directly on Android devices.

Our coverage measurement toolchain starts with the instrumentation of the application we want to test, which allows us to measure code coverage of the given application during test execution. As the device of the pilot project runs the Java-based Android operation system, Java instrumentation techniques can be used. Then, the test cases are executed and the coverage information is collected. In the pilot implementation, the collection is split between the Android device and the used testing tool RT-Executor [4]: the service collects the information from the individual applications of the device, while the testing tool processes the information (through its plug-ins).

![Fig. 1. Coverage collection methodology on the Set-Top-Box](image-url)
The coverage information gathered with the help of the coverage framework can be utilized by many applications in the testing methodology. They can be used for selecting and prioritizing test cases for further test executions, or for helping to generate additional test cases if the coverage is not sufficient. It is also useful for dead code detection or traceability links computation.

The rest of the paper is organized as follows. In Section 2, we give an overview on the related work. In Section 3, the implementation of the coverage measurement framework is presented. In Section 4, some use cases are presented to demonstrate the usefulness of coverage information. In Section 5, we summarize our achievements and elaborate on some possible future works.

2 Related Work

Software testing is a very important activity during the software development process. It helps reducing the risk of residual bugs and so contributes to the quality of the released software. Different testing techniques can be categorized by many criteria. One of these categories contain the dynamic testing methods where testing includes the execution of the program under test. There are two well known groups of dynamic testing techniques: black-box and white-box testing techniques. While black-box techniques help to assess the quality of the software under test, white-box techniques rather assess the quality of the executed test sets. A good test includes a wide range of testing techniques, combines them to lessen the weaknesses of the individual methods, and utilizes the advantages of the combination. For example, tests prepared using black-box techniques are usually measured for code coverage (a white-box technique), which helps to estimate the remaining risks more accurately.

In the CIRENE project, one of our first tasks was to assess the state-of-the-art in embedded systems testing techniques with special attention to the combined use of black and white-box techniques. We prepared a technical report on it [5]. In this paper, we report only a few number of combined testing techniques that have been specialized and implemented in the embedded environment.

Götlieb and Petit presented a path-based test case generation method [6]. They used symbolic program execution and did not execute the software on the embedded device prior to the test case definitions. We use code coverage measurement of real executions to determine information that can be used in test case generation.

José et al. defined a new coverage metric for embedded systems to indicate instructions that had no effect on the output of the program [7]. Their implementation used source code instrumentation and worked for C programs at instruction level, and had a great influence on the performance of the program. Biswas et al. also utilized C code instrumentation in embedded environment to gather profiling information for model-based test case prioritization [8]. We use binary code instrumentation at method level, use traditional metric that indicates whether the method is executed during the test case or not, and our
solution has a minimal overhead on execution time. The resulting coverage information can also be used for test case selection and prioritization.

Hazelwood and Klauser worked on binary code instrumentation for ARM-based embedded systems [9]. They reported the design, implementation and applications of the ARM port of the Pin, a dynamic binary rewriting framework. However, we are working with Android systems that hides the concrete hardware architecture but provides a Java-based one.

There are many solutions for Java code coverage measurement. For example, EMMA [3] provides a complete solution for tracing and reporting code coverage of Java applications. However, it is, as well as others are general solutions not concerning the specialities of Android or any embedded systems.

Most of the coverage measurement tools utilize code instrumentation. In Java-based systems, byte code instrumentation is more popular than source code instrumentation. There are many frameworks providing instrumenting functionalities [e.g. DiSL [10], InsECT [11,12], jCello [13], BCEL [14], etc.] for Java. These are very similar to each other regarding their provided functionalities. We chose Javassist [15] to be our instrumentation framework in the pilot project.

3 Coverage Measurement Toolchain

The implemented coverage measurement toolchain consists of several parts. First, the applications selected for measurement have to be prepared. The preparation process includes program instrumentation that inserts extra code in the application so that the application can produce the information necessary for tracing its execution path during the test executions. The modified applications and the environment that helps collect the results must be installed on the device under test.

Next, tests are executed using this measurement environment and the prepared applications, and coverage information is produced. In general, test execution can be either manual or automated. In the current implementation, we use the RT-Executor [4] for test automation. The RT-Executor is a black-box test automation tool developed for testing multimedia devices by RT-RK corporation in Novi Sad [16]. During the execution of the test cases, the instrumented applications produce their traces which are collected, and coverage information is sent back to the automation tool.

Third, the coverage information resulted from the previous test executions is processed and used for different purposes e.g. for test selection and prioritization, additional test case generation, traceability computation, and dead code detection.

In the rest of this section, we describe the technical details of the coverage measurement toolchain.

3.1 Preparation

In order to measure code coverage, we have to prepare the environment and/or the programs under test to produce the necessary information on the executed
items of the program. In our case, the Android system uses the Dalvik virtual machine to execute the applications. Although modifying this virtual machine to produce the necessary information would result in a more extensive solution that would not require the individual preparation of the measured applications, we decided not to do so, as we assumed that modifying the VM itself had higher risks than modifying the individual applications. With individual preparation it is much easier to decide what to measure and at what level of details. So, we decided to individually prepare the applications to be measured. As we were interested in method level granularity, the methods of the applications were instrumented before test execution, and this instrumented version of the application was installed on the device. In addition, a service application serving as a communication interface between the tested applications and the network was also necessary to be present on the device.

**Instrumentation** During the instrumentation process, extra instructions are inserted in the code of the application. These extra instructions should not modify the original functionality of the application except that they are logging the necessary information and slowing down the execution. Instrumentation can be done on the source code or on the binary code.

In our pilot implementation, we are interested in method level code coverage measurement. It requires the instrumentation of each method inserting a code that logs the fact that the method is called. As our targets are Android applications usually available in binary form, we have chosen binary instrumentation.

![Instrumentation toolchain](image)

**Fig. 2.** Instrumentation toolchain

Android is a Java-based system which in our case means that the applications are written in Java language and compiled to Java Bytecode before a further step creates the final Dalvik binary form of the Android application. The transformation from Java to Dalvik is reversible, so we can use Java tools to manipulate the program and instrument the necessary instructions. We used the **Javassist** [15] library for Java bytecode instrumentation, **apktool** [17] for unpacking and repacking the Android applications, the **dex2jar** [18] tool for converting between the Dalvik and the Java program representations, and **aapt** [19]
tool for sign the application. The *Instrumentation toolchain (see Figure 2)* is the following:

- The Android binary form of the program needs to be instrumented. It is an `.apk` file (a special Java package, similar to the `.jar` files, but extended with other data to become executable).
- Using the `apktool` the `.apk` file is unpacked and `.dex` file is extracted. This `.dex` file is the main source package of the application, it contains its code in a special binary format. [19,20]
- For all `.dex` files the `dex2jar` is used to convert them to `.jar` format.
- On the `.jar` files we can use the `JNIstrumenter`. The `JNIstrumenter` is our Java instrumentation tool based on the `Javassist` library [15].

`JNIstrumenter` first adds a new collector class with two responsibilities to the application. On the one hand, it contains a coverage array that holds the numbers indicating how many times the methods (or any other items that is to be measured) were executed. On the other hand, this class is responsible for the communication with the service layer of the measurement framework.

Next, the `JNIstrumenter` assigns a unique number as ID to each of the methods. This number indicates the method’s place in the coverage array of the collector class. Then a single instruction is inserted in the beginning of all methods which updates the corresponding element of the coverage array on all executions of the method.

The result of the instrumentation is a new `.jar` file with instrumented methods and another file with all the methods’ names and IDs.

- The instrumented `.jar` files are converted to `.dex` files using the `dex2jar` tool again.
- Finally, the `.apk` file instrumented application is created by repacking the `.dex` files with the `apktool` and signing it with the `aapt` tool.

During the instrumentation, we give a name to each application. This name will uniquely identify the application in the measurement toolchain, so the service application can identify and separate the coverage information of different applications.

After the instrumentation, the application is ready for installation on the target device.

**Service application** In our coverage measurement framework implementation it is necessary to have an application that is continuously running on the Android device in parallel with the program under test. During the test execution, this application is serving as a communication interface between the tested applications and the external tool collecting and processing the coverage data. On the one hand this is necessary because of the rights management of the Android systems. Using the network requires special rights from the application and it is much simpler and more controllable to give these rights to only a single application than to all of the tested applications. On the other hand, this solution
provides a single interface to query the coverage data even if there are more applications tested and measured simultaneously.

In Android systems, there are two types of applications: “normal” and “service”. Normal applications start, do something while they are visible on the screen, and are destroyed on closing. Services are running in the background continuously and are not destroyed on closing. So, we had to implement this interface application as a service. It serves as a bridge between the Android applications under test and the “external world” as it can be seen on Figure 3. The tested applications are measuring their own coverage and the service queries these data on-demand. As the communication is usually initiated before the start and after the end of the test cases, this means no regular communication overhead in the system during the test case executions.

![Diag: Service Layer](image)

**Fig. 3. Service Layer**

Messages are accepted from and sent to the external coverage measurement tools. The communication uses JSON [21] objects (type-value pairs) over the TCP/IP protocol. Implemented messages are:

- **NEWTC** The testing tool sends this message to the service to sign that there is a new test case to be executed and asks it to perform the required actions.
- **ASK** The testing tool sends this message to query the actual coverage information.
- **COVERAGE DATA** The service sends this message to the testing tool in response to the **ASK** message. The message contains coverage information.

Internally, the service also uses JSON objects to communicate with the instrumented applications. Implemented messages are:

- **reset** The service sends this message to the application to reset the stored coverage values.
ask  The service sends this message to query the actual coverage information.
coverage data The application sends this message to the service in response to the ask message. The message contains coverage information.

Installation  To measure coverage on the Android system, two things need to be installed: the particular application we want to test and the common service application that collects coverage information from any instrumented application and provides a communication interface for querying the data from the device.

The service application needs to be installed on a device only once; this single entity can handle the communication of all tested applications.

The instrumented version of each application that is going to be measured must be installed on the Android device. The original version of such an application (if there was one) must be removed before the instrumented version can be installed. It is necessary because Android identifies the applications by their special android-name and package, and our instrumentation process does not change these attributes of the applications; it only inserts the appropriate instructions into the code. Our toolchain uses the adb tool (can be found in Android Development Kit) to remove and install packages.

3.2 Execution

During test execution, the Android device executes the program under test and the service application simultaneously. The program under test counts its own coverage information and sends this information when the service layer application asks for it. The coverage information can be queried from this service layer application through network connection. We implemented a simple query interface in Java for manual testing and a plugin for the RT-Executor [4] (a black-box test automation tool we used in this project) for automated testing.

In our pilot project, we used two possible modes of test execution: manual and automatized. Either mode is used, the service layer application must be started prior to the beginning of the execution of the test cases. It is done automatically by the instrumented applications if the service is not running already.

In the case of automated testing, the RT-Executor reads the test case scripts and executes the test cases. The client side of the measurement framework is contained in a plug-in of the automation tool and this plug-in must be controlled from the test case itself. Thus, the test case scripts must be prepared in order to measure the code coverage of the executed applications.

The plug-in can indicate the beginning and the end of the particular test cases to the service, so the service can distinguish the test cases and can separate the collected information. In order to measure the test case coverages individually, one instruction must be inserted in the beginning of the test script to reset the coverage values and one instruction must be inserted in the end instructing the plug-in to collect and store coverage information belonging to the test case.

During test execution the following steps are taken:

- Start the program under test.
The start of the program triggers the start of the measurement service if necessary. Then the program under test connects to the service and registers itself by its unique name given to it in instrumentation process.

The test automation system starts a test case. The test case forces the automation system plug-in to send a NEWTC message to the service. The service sends the reset message to the program under test. The PUT resets the coverage array in its collector class. The service returns the actual time to the plug-in.

The test automation system performs the test steps. The PUT collects the coverage data.

The test case ends. The automation tool plug-in sends the ASK signal to the service. The service sends the ask signal to the PUT. The PUT sends back the coverage data to the service. The service sends back the coverage data and the actual time to the automation tool plug-in.

The plug-in calculates the necessary information from the coverage data and stores it in the local files. The stored data are: execution time, trace length, coverage value, lists of covered and not covered methods. Another plug-in decides if the test case was passed or failed and stores this information in other local files.

These steps are repeated during the whole test suite execution. At the end, the coverage information of all the executed test cases are stored in local files and are ready to be processed by different stages of the testing methodology.

3.3 Processing the Data

As we mentioned above, the client side of the coverage measurement system is realized as a plug-in of the RT-Executor tool.

The plug-in is controlled from the test cases. It indicates the beginning and the end of a test cases to the service layer application. The service replies to these signals by sending the valuable data back. When the measurement client indicates the start of a test case (by sending the NEWTC message to the service), the service replies with the current time which is stored by the client. At the end of a test case (when the ASK signal is sent by the client), the service replies with the current time and the collected coverage information of the methods.

When the coverage data is received, the measurement client computes the execution time, trace length (the number of method calls), and the list of covered and not covered methods’ IDs. Then, the client stores these data in a result file for further use. The client makes other files, the trace files, separately for each test case. Such a trace file stores the identifiers of the methods covered during the execution of the test case.

As an alternative client, we implemented a simple standalone java application that is able to connect to the measurement service (and this way it replaces the RT-Executor plug-in). This client is able to visualize the code coverage information online, and is useful during the manual testing activities (e.g. during exploratory tests).
3.4 Applications on the Measurement Framework Results

The code coverage and other information collected during the test execution can be used in various ways. In the pilot project, we implemented some of the possible applications. These implementations process the data files locally stored by the client plug-in.

**Test Case Selection and Prioritization** Test case selection is a process that defines a subset of a test suite based on some properties of the test cases. Test case prioritization is a process that sorts the test suite elements according to their properties [22]. A prioritized list of test cases can be cut at some points resulting in a kind of selection.

Code coverage data can be used for test case selection and prioritization. We implemented some selection and prioritization algorithms as a plug-in of the RT-Executor, which utilizes the code coverage information collected by the measurement framework:

- A change-based selection algorithm was implemented that used the list of changed methods and the code coverage information to select the test cases that covered some of the changed methods. Executing the selected test cases can only reduce the time required for regression test execution while the failure detection capability of the suite is not reduced.
- We implemented two well-known coverage-based prioritization algorithms: one that prefers test cases covering more methods; and another that aims at higher overall method coverage with less test cases.
- We also implemented a simple prioritization that used the trace length of the test cases. It can prioritize the tests either in the descending or the ascending order of the length of their traces.

**Not Covered Code** Not covered code plays an important role in program verification. There are two possible reasons for a code part not being covered by any test case executions. The test suite can simply omit its test case, in which
case we have to define some new test cases executing the missed code. It can also happen that the not covered code cannot be executed by any test cases, which means that it is a dead code. In the latter case, the code can be dropped from the codebase.

In our pilot implementation, automatic test case generation is not implemented. We simply calculate the lists of methods covered and not covered during the tests. These lists can be used by the testers and the developers to examine the methods in question and generate new test cases to cover the methods, or to simply eliminate the methods from the code.

**Traceability Calculation** Traceability links between different software development artifacts play a very important role in the change management processes. For example, traceability information can be used to estimate the required resources to perform a specific change or to select the test cases related to the change of the specification. Relationship exists between different types of development artifacts. Some of them can simply be recorded when the artifact is created, some of them must be determined later.

We implemented a very simple traceability calculator that computes the correlation between the requirements and the methods, based on the pre-defined relationships between the requirements and the test cases and between the test cases and the methods (code coverage). If a requirement-method pair is assigned with high correlation, we can assume that the required functionality is implemented in the method. This information can be used to assess the number of methods to be changed if the particular requirement changes.

4 Usage and Evaluation

In this section, we present and evaluate some use cases to demonstrate the usability of the measurement toolchain.

4.1 Additional Test Case Generation

In the pilot project our target embedded hardware was an Android-based Set-Top-Box. We had this device with different pre-installed applications and test cases for some of these apps. A media-settings application was selected for testing our methodology and implementation. After executing the tests of this application with coverage measurement, we found that the pre-defined tests covered only 54% of the methods. We examined the methods and defined new test cases. Although the source code of this applications was not available, based on the not covered method names and the GUI, we were able to define new test cases that raised the number of covered methods to 69%. This is still less than the required 100% method level coverage, but shows that the feedback on code coverage can be used to improve the quality of the test suite.
4.2 Traceability Calculation

In the pilot project a simple implementation that is able to determine the correlation between the code segments and the requirements was made. We did not conduct detailed experimentation in this topic, but we did test the tool. Instead of the requirements, we defined 12 functionalities performed by three media applications (players) on our target Set-Top-Box device. Then, we assigned these functionalities to 15 complex black-box test cases of the media applications and executed the test cases with coverage measurement. The traceability tool computed correlations between the 12 functionalities and 608 methods, and was able to separate the methods relevant in implementing a functionality from the not relevant methods.

5 Conclusions and Future Work

In this paper, we presented a methodology for method level code coverage measurement on Android-based embedded systems. Although there were more solutions allowing the measure of the code coverage of Android applications on the developers' computers, no common methods were known to us that performed coverage measurement on the devices. We also reported the implementation of this methodology on a digital Set-Top-Box running Android. The coverage measurement was integrated in the test automation process of this device allowing the use of the collected coverage data in different applications like test case selection and prioritization of the automated tests, or additional test case generation.

There are many improvement possibilities of this work. Regarding the implementation of code coverage measurement on Android devices, we wish to examine if the granularity of tracing could be fined to sub-method level (e.g. to basic block or instruction levels) without significantly affecting the runtime behaviour of the applications. This would allow us to extract instruction and branch level coverages that would result in more reliable tests. We are also thinking of improving the instrumentation in order to build dynamic call trees for further use. The current implementation (simple coverage measurement) does not need to deal with timing, threads and exception handling, both of which are necessary for building the more detailed call trees. It would also be interesting to help the integration of this coverage measurement in commonly used continuous integration and test execution tools.

We are also examining the utilization possibilities of the resulting coverage data. For example, traceability information between code and the visible graphical elements could be established, and this information might help to partially automate collecting data for usability tests and to establish usability models. The implemented code coverage measurement and the testing process that utilizes this information are a good base for measuring the effect of using coverage measurement data on the efficiency and reliability of testing. We are planning to conduct researches in these topics.
